Abstract

Introduction: Huntington's disease (HD) is an incurable neurodegenerative disorder that manifests progressive behavioral and motoric changes and cognitive dysfunction. It is caused by CAG expansion in huntingtin gene and has almost full penetrance. The striatum is the most affected tissue in HD, but pathological changes are also detected in the peripheral tissues like blood, skeletal muscle or fibroblasts. Intensive HD research in the last years has revealed an important role of mitochondrial dysfunction in the pathogenesis and progression of the disease, which includes changes in the activity of the respiratory chain complexes, ATP synthesis or increased apoptotic stimuli. *Aim and material:* We decided to analyse the amount of mitochondrial respiratory chain complex I and IV in the epithelial cells of buccal smear in six HD patients and from an animal disease model, minipigs transgenic for the N-terminal part of human mutated huntingtin (TgHD). *Methods:* The amount of mitochondrial complexes I and IV was determined by dipstick microimmunocapture assay (Mitosciences). *Results:* A decreased level of CI and/or CIV in HD patients (4/6), up to 36% of the control values, was detected. The analysis performed on the minipig samples showed strong signals, but no uniform trend was observed within the WT and TgHD groups at the age of 36 months. *Conclusions:* The advantage of this approach is that samples of buccal cells can be collected repeatedly without the stress for the studied objects and therefore can serve for longitudinal monitoring of mitochondria during the asymptomatic stage until full development of the disease.

Key words

Klíčová slova

Souhrn

Úvod: Huntingtonova nemoc (Huntington's Disease; HD) je neléčitelné neurodegenerativní onemocnění, které se manifestuje v dospělosti progresivními změnami chování, motoriky a kognitivních funkcí. Onemocnění je způsobeno expanzí tripletu CAG v genu pro protein huntingtin a má téměř úplnou penetranci. Nejvíce postižené bývá striatum, avšak patologické změny jsou detekovatelné také v periferních tkáních jako je krev, sval nebo kožní fibroblasty. V posledních letech se ukazuje, že důležitou roli v patogenezi a progresi HD hraje poškození mitochondrií, jako jsou např. změny aktivit komplexů dýchacího řetězce, snížení syntézy ATP nebo zvýšení apoptotických signálů. *Cíl a materiál:* Cílem studie bylo analyzovat množství komplexu I a IV dýchacího řetězce v epiteliálních buňkách bukálního stěru u šesti pacientů s HD a u tří miniprasat transgenních pro N-terminální část lidského mutovaného huntingtinu (TgHD) ve srovnání se zdravými kontrolami. *Metody:* Množství komplexu I a IV dýchacího řetězce bylo stanoveno pomocí mikroimunoanalýzy (Dipstick microimmunocapture assay, Mitosciences). *Výsledky:* U čtyř pacientů ze šesti bylo detekováno snížené množství komplexu I a/nebo IV až na 36 % hodnoty u kontrol. Mikroimunoanalýza se ukázala dostatečně citlivá i pro detekci komplexů I a IV v buňkách bukální sliznice TgHD miniprasat, avšak ve věku 36 měsíců nebyl zaznamenán rozdíl v obsahu komplexů I a IV mezi TgHD a WT zvířaty. Vzorky z bukálního stěru mohou být odebírány opakovaně bez větší zátěže pacienta nebo sledovaného zvířete. Analýza epiteliálních buněk ústní sliznice tak může sloužit k dlouhodobému monitorování mitochondrií od asymptomatického období až po úplný rozvoj HD.

Introduction

Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder usually affecting adult people between 30 and 50 years of age. HD is characterized by slow changes in behavior and personality, motoric changes and progressive dementia [1]. The mean duration of HD is 17–20 years and is caused by the pathological expansion of a CAG repetition on chromosome 4 in coding area of the gene for protein huntingtin (Htt) [2]. A normal polyglutamine Htt tract contains 10–35 glutamines; HD patients usually carry more than 40 CAG repetitions [3]. The onset and course of the disease are, to some extent, influenced by the number of repeats, where a higher CAG number means earlier onset and faster progression [4].

Htt is important for brain development, neuronal function and neuronal stability [5]. The brain, especially the striatum, is the tissue most affected by HD. Intensive research in this area has revealed new functions of Htt and connected them with a variety of cellular processes not only specific for neurons. One example of such a connection is the mitochondrial link of Htt functions and HD. It is known that Htt binds to the outer membrane of the mitochondria and impacts fusion/fission machinery. Htt also influences the transcriptional factor Peroxisome proliferator-activated receptor γ coactivator-1α (PGC1–α), which manages mitochondrial energy metabolism in many ways, which leads to changes in whole cellular physiology [6]. The mitochondria's connection to HD has been intensively studied, and the disease is linked to many mitochondrial disturbances, such as the decreased activity of respiratory chain complex II (CII) [7], decreased oxygen consumption [8] and ultrastructural changes in neuronal tissues [9]. Pathological disturbances in HD are not strictly connected only to neuronal tissues, and the peripheral tissues are now a focus of interest [10]. The mitochondrial pathology in the peripheral tissues has been described in muscle [10], the heart [11], lymphocytes [12] and fibroblasts [13], as well as in the testes [14]. In order to find a specific marker that could monitor the course of disease in HD, particularly in non-invasive tissue, we decided to test the cells of buccal smear.

In our study, we determined the amount of mitochondrial respiratory chain complex I (CI) and complex IV (CIV) in buccal epithelial cells obtained from HD patients and from animal disease model, minipigs transgenic (TgHD) for the terminal part of human mutated huntingtin.

Materials and methods
Patients

The experimental group consisted of six HD patients and two healthy adult controls. In the patient group, there were three men and three women between the ages of 34 and 66 years. All patients were symp-

Tab. 1. CAG number, age of onset and clinical manifestation of tested patients with HD.

Patient	Sex	CAG number	Age at disease onset (years)	Disease duration (years)	Clinical manifestation
P1	female	19/42	49	8	chorea, postural instability, irritability and verbal aggression, cognitive deficit
P2	male	20/43	50	9	chorea, postural instability, verbal aggression, cognitive deficit
P3	female	17/44	58	7	mild generalized chorea
P4	male	16/53	24	8	chorea, postural instability, dysphagia, malnutrition
P5	female	19/43	34	13	chorea, dystonia, dysarthria, irritability, cognitive deficit, malnutrition
P6	male	17/48	22	11	chorea, mild postural instability

tomatic, heterozygote HD patients, in which the CAG repeat number on the mutated allele varied between 42 and 53. The number of CAG repeats and the course of the disease corresponded to the classical form of HD in all cases. Informed consent was obtained from patients prior to taking samples, and the Ethical Committee of the General University Hospital in Prague approved the study. The detailed information of each patient, such as the age of disease onset and symptoms, are summarized in Tab. 1.

Animals

Transgenic minipigs with the N-terminal part of the human mutated huntingtin [27] were studied. The transgenic (n = 3, marked K63, K100 and K104) and wild type (WT) controls (n = 3, marked K48, K64 and K103) at the age of 36 months were used in experiments. K48, K100 were females, K64, K103, K104, K63 were males. All components of this study were carried out in accordance with the Animal Care and Use Committee of Institute of Animal Physiology and Genetics and were conducted according to current Czech regulations and guidelines for animal welfare and with approval by the State Veterinary Administration of the Czech Republic.

Sample collection and analysis

Buccal epithelial cells were obtained non-invasively from patients, healthy controls, TgHD and wild type animals for this study. Buccal epithelial cells were collected using a sterile OmniSwab (Ct. No. WB100035, Whatman, Whatman/GE Healthcare Europe GmbH, Freiburg, Germany). The OmniSwab brush was used to scrape the inside of both cheeks. The scrape was provided gently to prevent blood contamination of the sample because of injury. The cotton brush with the collected cells was transferred into a clean microtube and stored at –80 °C until use.

The expression of Htt and mtHtt in buccal epithelial cells from samples taken from the patients and animals was verified using electrophoretic separation (Fig. 1), the visualisation of Htt and mtHtt was done by the N-terminal unit of huntingtin antibody (EPR5526, Abcam).

Dipstick immunocapture analysis

Dipstick immunocapture analysis (DIA) kits were used to determine the level of mitochondrial CI and CIV in buccal epithelial cells (ab109722, ab109877, Complex I and IV Human Protein Quantity Dipstick Assay Kit,

Abcam). All procedures were carried out according to conditions determined in our previous study [16] and the manufacturer's instruction, with minor modifications, as mentioned briefly below. Buccal cell isolation was performed by adding 600 μl of buffer A (ab109722 or ab109877, these solutions are interchangeable) and a 1% protease inhibitory cocktail (PIC, Sigma-Aldrich, St. Louis, MO) to an Eppendorf tube (Eppendorf, Hamburg, Germany) containing a swab with the collected buccal epithelial cells. The tube was incubated on ice with frequent mixing (every 5 min) for 1 hour and then centrifuged at 15,000 g for 20 min at 4°C. The supernatant (the buccal cell lysate) was used for further analyses or stored at –80 °C until use.

For the dipstick analysis, 100 μg of protein per buccal cell lysate sample was diluted into 50 μl in buffer A. A volume of 25 μl of buffer B was added to the sample, and the mixture was transferred to a microplate well containing a dried gold-conjugated antibody (ab109722 or ab109877). After antibody rehydration, the dipstick was added, and sample was wicked onto it. Then, 30 μl of buffer C was added to the well to wash the high background away from the dipstick. The dipstick was dried and scanned. The signal intensity of CIV/CI was analysed using the Quantity One 1–D Analysis Software (Bio-Rad Laboratories, Hercules, CA). The results of two independent measurements conducted under the same conditions were evaluated separately using the Quantity One 1–D Analysis Software (Bio-Rad Laboratories), and the resulting scores were averaged and interpreted. The signal intensities of the patient samples were expressed in percentage units. The signal intensities of the minipig samples were expressed in absolute values.

Results
Patient testing

DIA (ab109722, ab109877, Abcam) was used to determine the amounts of CI and CIV in buccal epithelial cells obtained from six HD patients and two adult healthy controls. The results of two independent measurements obtained under the same conditions were evaluated separately using the Quantity One 1-D Analysis Software (Bio-Rad Laboratories), and the scores were averaged and interpreted.

The amount of CI was decreased in four patients (P3, P4, P5 and P6). The amount of CI in the buccal epithelial cells of patients P1 and P2 was at the lower limits of the con-

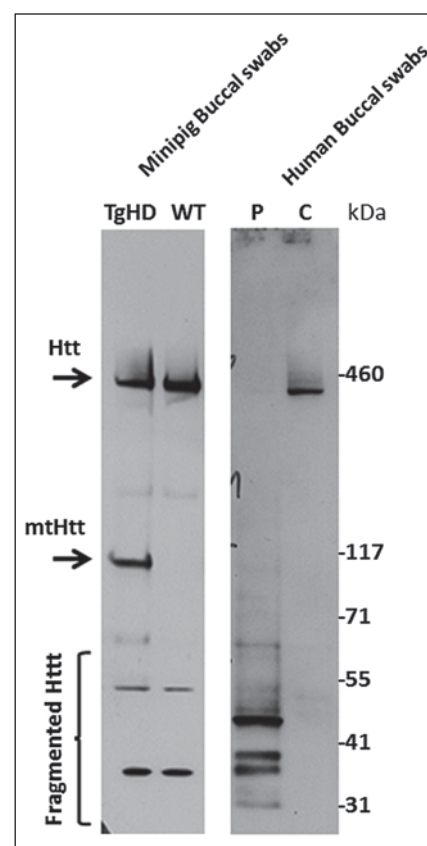

Fig. 1. Huntingtin expression in buccal epithelial cells of minipigs transgenic for N-terminal part of human mutated huntingtin and patients with HD.

The cell lysates were separated by SDS--PAGE and detected by the EPR5526 antibody. Image serves as an illustrative proof of huntingtin expression in the buccal swab and was carried out on samples outside the studied group (TgHD L98, WT L89, P7, C4). The fragmentation of Htt is in accordance to previously published data and is detectable in symphomatic phase of HD [15].

TgHD – transgenic minipig with N-terminal part of mutated human huntingtin, WT – wild type control minipig, P – patient, C – control, Htt – normal huntingtin, mtHtt – mutated huntingtin protein.

trol values (Fig. 2A). The amount of CI in patients P1, P2, P3, P4, P5, and P6 was 86%, 76%, 71%, 70%, 62%, and 36% of the control values, respectively.

The determination of the amount of CIV in the buccal epithelial cells showed a decreased level in four patients (P1, P3, P4 and P6) in comparison to controls. The values for the amount of CIV in patients P2 and P5 were near the low borderline values of the controls. The levels of CIV in the patients P1, P2,
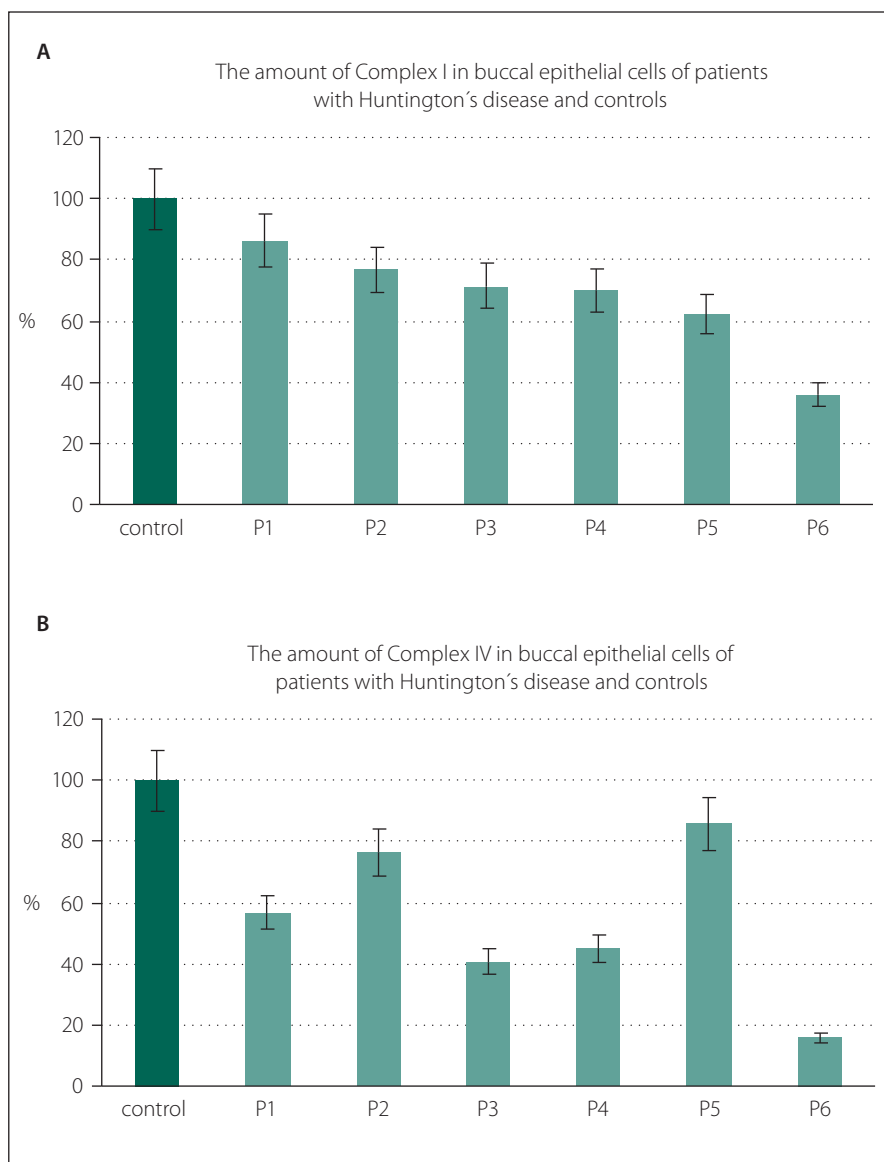

Fig. 2. The amount of mitochondrial respiratory chain complex I (A) and complex IV (B) in the buccal epithelial cells in six patients with HD and healthy controls.

The results are expressed as the average of two experiments using the same procedure that is used for the DIA kits (ab109877 and ab109722, MitoSciences). The amount of protein used in each assay was 100 μg, and the results were evaluated using the Quantity One 1-D Analysis Software (Bio-Rad Laboratories). The control bar represents the mean of signal intensity of two controls and is expressed as 100%.

The signal intensity of CIV was 111.9 for WT K48, 75.4 for WT K64, and 83.4 for WT K103. In the TgHD group, the signal intensity varied from 58.1 for TgHD K63, crossed to 93.9 for TgHD K100, and then went up to 157.5 for TgHD K104.

Discussion

Although we know the cause of HD and the research in this field is very intensive, neurodegenerative HD is still an incurable disease. One of many important players in HD pathology are the mitochondria and their energy metabolism, which is responsible for the synthesis of more than 90% of ATP for cellular processes. Mitochondrial disturbances in HD are studied primarily in neurons [17], where the impact is most evident and the view is usually functional [18].

The evidence for the involvement of mitochondria in HD comes from post-mortem, *in vivo* and *in vitro* studies. A defect in the activity of the OXPHOS complex IV was found specifically in the caudate and putamen of the brains of HD patients [19], the striatum of mtHtt transgenic (mtHtt-Tg) mice [20] or in the muscle of R6/2 muscle mice [21]. The mitochondrial-encoded COX I subunit of CIV was decreased in the platelets of both pre-HD and symptomatic HD carriers [22]. Complex I was affected in the muscles [23,24] and platelets of HD patients [22,23].

In our study, we focused on mitochondrial disturbances in the peripheral tissues of HD patients, specifically in buccal epithelial cells. We determined the amount of mitochondrial CI and CIV using DIA kits (Abcam). Parallel to patient testing, we also analysed the buccal epithelial cells from a TgHD minipig model. The DIA method that was utilized in our previous study on patients with COX deficiency was optimized for buccal epithelial cells [16].

In our study, in the HD patient samples, we detected a decrease in the amount of CI and/or CIV in 4/6 tested patients in comparison to the controls. The amount of CI varied between 60% and 80% of the control values, and the amount of CIV in four cases was less than 60% of the controls (Fig. 2B). Unfortunately, we do not have any available tests to check the functionality of the oxidative phosphorylation system of buccal cells. However, we can compare the data with similar DIA analysis provided by the fibroblasts of another HD patient group, where the amounts of CI and CIV were lower than

P3, P4, P5, and P6 were 56%, 76%, 40%, 45%, 86%, and 16% of control values, respectively (Fig. 2B).

Minipig testing

DIA (ab109722, ab109877, Abcam) was used to determine the amounts of CI and CIV in the buccal epithelial cells obtained from a minipig model transgenic for HD. We tested three WT and three TgHD animals The method used provided strong signals in the

minipig model cells, and the results can be clearly evaluated.

The inter-individual variabilities of the results were obtained, and a uniform trend was not observed within the WT and TgHD groups. The raw data (absolute values) from the analysis showed signal intensity for CI of 78.9 for WT K48, 51.5 for WT K64, and 30.6 for WT K103. The intensity of the signal of the TgHD group was 38.4 for TgHD K63, 25.2 for TgHD K100, and 96.8 for TgHD K104.
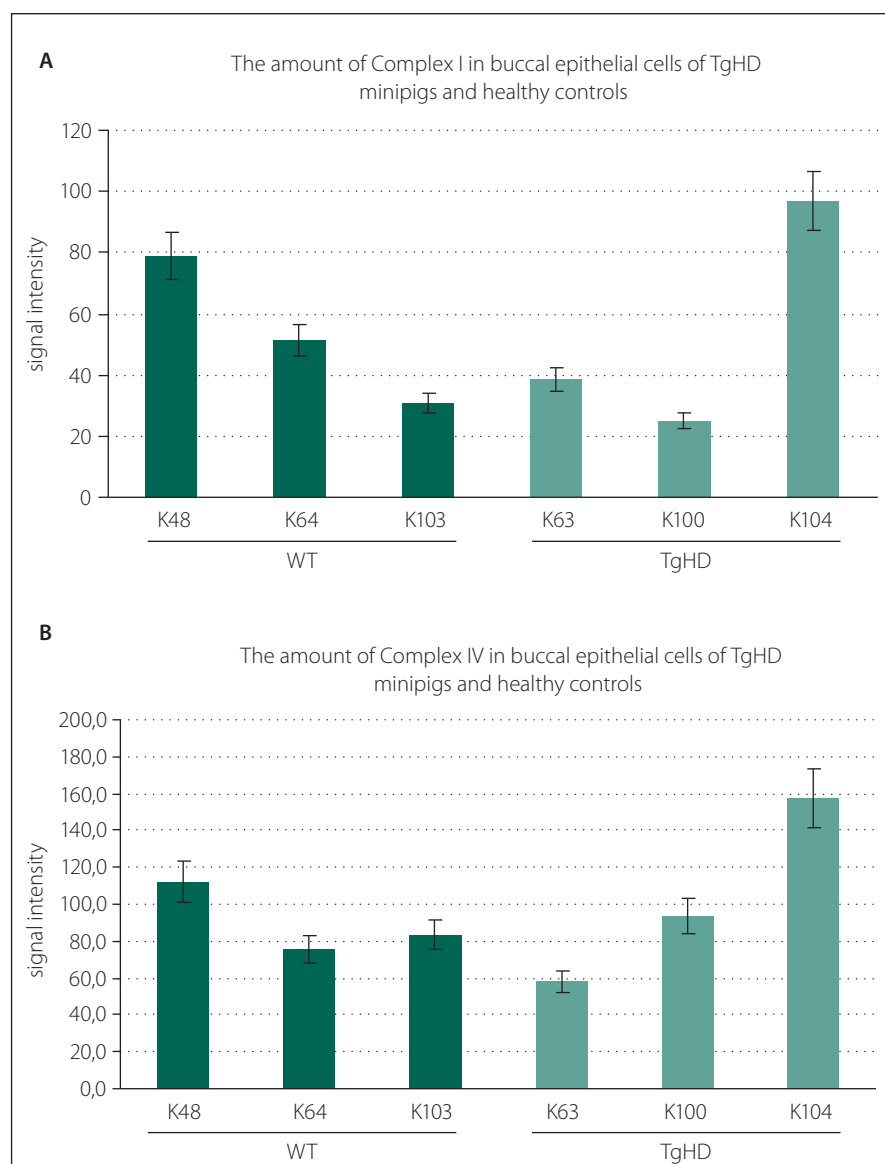

Fig. 3. The amount of the mitochondrial respiratory chain complex I (A) and complex IV (B) in the buccal epithelial cells of TgHD minipigs and wild type controls at the age of 36 months.

The results are expressed as the average of two experiments using the same procedure as that used for the DIA kits (ab109877 and ab109722, MitoSciences). The amount of protein used in each assay was 100 μg, and the results were evaluated using the Quantity One 1-D Analysis Software (Bio-Rad Laboratories). The output is the signal intensity, which is expressed in absolute values.

the electron transport complexes, resulting in mitochondrial dysfunction. In addition, it is known that there is mtDNA damage in HD [26], and thus, the impaired synthesis of the mitochondrial-encoded subunits may contribute to the reduced content of the subunits of the respiratory chain complexes. Silva et al. described a decrease in the mt-encoded COX I subunit in the platelets in both pre-HD and symptomatic HD carriers [22].

The results from the analysis of the amount of CI and CIV in the 36-month-old minipig model did not show any differences between WT and TgHD individuals (Fig. 3A, 3B). The probable cause of this is the young age of the tested animals, unlike the HD patients, they are still in the presymptomatic stage of the development of the disease. It will be necessary to carry out this study on a larger group of animals.

The advantage of the method used in this study is that samples of buccal cells can be collected repeatedly without causing stress for the studied objects. Therefore, this method can serve as a longitudinal monitor of the mitochondria during the asymptomatic stage until the full development of the disease. Especially in TgHD model, buccal smears could be used for monitoring a specific marker of the disease and an eventual development of the therapies.

Although our study has many limitations, the method used is quick, simple and sensitive. It can also be used in other peripheral tissues, such as lymphocytes, muscle or fibroblasts, for the analysis of the amount, and in many cases, the activity of CI and CIV in patients with HD or suspected mitochondrial disease. It can now serve as an additional method for the mapping of mitochondrial disturbances in the peripheral tissues in HD patients.

Our study and its results are not extensive enough for general conclusions, but it could serve as a pilot study for a new direction in the research on the mitochondrial connection to HD.

80% of the control values in 6/8 patients and the measurement of the specificic activity of CI and CIV did not show any significant differences between patients and controls (data not shown). We suppose that the changes in the CI and CIV protein amounts in the peripheral tissues do not impair function because the enzymes still gain to cover their activities from their reserve capacity. Nevertheless, it could indicate pathological changes connected with HD. The CI and CIV are multi-subunits, and their synthesis is controlled by both mitochondrial and nuclear DNA. For the proper fully assembled complex holoenzyme, it is necessary for the subunits synthesised in the cytosol to be transported into the mitochondria. It has been shown that mtHtt affects the transport of cytosolic proteins into the mitochondria [25]. In parallel, it is not unreasonable to suggest that the genetic HD mutation may alter nuclear-encoded components of
