Optical coherence tomography measurements of the optic nerve head and retina in newly diagnosed idiopathic intracranial hypertension without loss of vision

Měření terče zrakového nervu a sítnice pomocí optické koherentní tomografie u nově diagnostikované idiopatické intrakraniální hypertenze bez ztráty zraku

Abstract

Aim: Idiopathic intracranial hypertension (IIH) is characterized by elevated intracranial pressure (ICP), usually in young, obese women with no circulatory pathology. We investigated the relationship between optical coherence tomography (OCT) measurements and cerebrospinal fluid (CSF) opening pressure in newly diagnosed IIH patients who have not been treated yet. *Material and methods:* The study included 19 individuals diagnosed with IIH and 22 healthy individuals in the control group. We measured the retinal nerve fibre layer (RNFL), fovea (F) and ganglion cell complex (GCC) thickness as well as the optic nerve head parameters in both groups. *Results:* The mean RNFL and F thicknesses were significantly higher in the patient group compared to the control group ($P < 0.01$). There was no statistical difference in mean GCC thickness between the patient and control groups. When RNFL thickness was compared by quadrant, the IIH patients had significantly higher values in all quadrants. In the patient group, the parameters that correlated positively with CSF opening pressure were papilloedema grade (rho = 0.869, $P < 0.01$), duration of symptoms (rho = 0.458, $P = 0.049$) and body mass index (rho = 0.653, $P = 0.002$). *Conclusion:* Increased peripapillary RNFL and F thickness measured by OCT is associated with elevated ICP in newly diagnosed IIH patients. OCT may thus serve as a valuable supplement to the subjective assessment of papilloedema in patients suspected of having IIH.

Souhrn

Cíl: Idiopatická intrakraniální hypertenze (IIH) je charakterizována zvýšeným intrakraniálním tlakem (intracranial pressure; ICP), a to obvykle u mladých obézních žen bez patologie oběhového systému. Zkoumali jsme vztah mezi měřeními optické koherentní tomografie (optical coherence tomography; OCT) a otevíracím tlakem mozkomíšního moku (cerebrospinal fluid; CSF) u nově diagnostikovaných pacientů s IIH, kteří dosud nebyli léčeni. *Materiál a metody:* Do studie bylo zařazeno 19 osob s diagnózou IIH a 22 zdravých osob v kontrolní skupině. V obou skupinách jsme měřili tloušťku vrstvy nervových vláken sítnice (retinal nerve fibre layer; RNFL), fovey (F) a komplexu gangliových buněk (ganglion cell complex; GCC) a parametry terče zrakového nervu. *Výsledky:* Průměrné tloušťky RNFL a F byly výrazně vyšší ve skupině pacientů než v kontrolní skupině (p < 0,01). V průměrné hodnotě tloušťky GCC nebyl mezi pacienty a kontrolní skupinou žádný statistický rozdíl. Při porovnání tloušťky RNFL podle kvadrantů měli pacienti s IIH výrazně vyšší hodnoty ve všech kvadrantech. Ve skupině pacientů byly parametry pozitivně korelujícími s otevíracím tlakem CSF stupeň edému papily (rho = 0,869, p < 0,01), doba trvání symptomů papily (rho = 0,458, p = 0,049) a index tělesné hmotnosti (rho = 0,653, p = 0,002). *Závěr:* Zvýšená tloušťka peripapilární RNFL a F naměřená pomocí OCT je u nově diagnostikovaných pacientů s IIH spojená se zvýšeným ICP. OCT tak může u pacientů s podezřením na IIH sloužit jako cenný doplněk při subjektivním hodnocení edému papily.

Introduction

Idiopathic intracranial hypertension (IIH) is caused by elevated cerebrospinal fluid (CSF) pressure of unknown aetiology. The annual incidence has been estimated in literature to be at most 3/100,000. IIH mainly affects young obese females, and in the majority of cases, it causes papilloedema due to increased intracranial pressure (ICP). Long-term papilloedema results in optic nerve atrophy, which may cause permanent vision loss [1]. Swelling of the optic nerve head (ONH) is believed to arise from compression of the retro-laminar optic nerve, which obstructs the axoplasmic flow [2]. Vision loss occurs in 86% of IIH patients and visual deficits can be severe in 10% of cases [3]. Causes of visual impairment in IIH patients include optic neuropathy, chorioretinal folds, hyperopic shift, haemorrhages, macular oedema and subretinal neovascularization. Visual loss in IIH may be reversible if treatment is timely but can be permanent in up to 40% of patients [4].

Optical coherence tomography (OCT) is an easy, quick and non-invasive technique that uses infrared light to obtain *in vivo* images of the macula and ONH similar to histological resolution. OCT has enabled the detection of abnormalities of the peripapillary retinal nerve fibre layer (RNFL) in newly diagnosed and chronic IIH. OCT has proved to be a powerful tool for accurately monitoring of the ONH volume [5,6] and neuro-axonal retinal damage [7–11]. Spectral-domain OCT (SD-OCT) provides continuous variable measurements that demonstrate structural changes in the optic nerve and retina associated with papilloedema and measures the effects of intracranial hypertension and its treatment.

This study had two aims: to evaluate whether OCT can be used to assess the retina and optic nerve in the newly diagnosed IIH population and to investigate the relationship between changes in CSF pressure and OCT parameters.

Materials and methods

This prospective observational study was conducted in consecutive patients with suspected IIH referred to Alaaddin Keykubat University Education and Research Hospital, Turkey, for lumbar puncture (LP). All patients were newly diagnosed and had not previously received medical treatment for IIH.

The inclusion criteria were age > 18 years, high CSF opening pressure ($\geq$ 25 cm H_2O), normal MRI and MRI venography, normal CSF composition and cytology, normal neurological examination except for papilloedema and probable or definite IIH with papilloedema according to the modified Dandy criteria [12]. Patients who had other ocular or neurological diseases or other medical conditions were excluded from the study. The controls were healthy volunteers with no abnormalities in a brief neuroophthalmologic examination including tonometry, slit-lamp examination and

funduscopy. The study was approved by the Ethics Committee of the Alaaddin Keykubat University Faculty of Medicine in Alanya, Turkey. Written informed consent was obtained from all participants in accordance with the Declaration of Helsinki.

All subjects underwent a complete ophthalmologic examination including best-corrected visual acuity (Snellen), colour vision testing (Ishihara's), visual field analysis with standard automated perimetry (Octopus 300 series V5.14 [Haag-Streit, Köniz, Switzerland]), Goldmann applanation tonometry, slit-lamp anterior segment examination, dilated fundus examination with a 90-D lens and mydriatic optic nerve and macular OCT imaging with RTVue SD-OCT system (RTVue-XR 100 Avanti software v.0.14 [Optovue, Inc., Fremont, CA, USA]). The severity of the papilloedema was graded using the Frisen scale. All ophthalmic examinations and measurements were performed by the same physician (F. A.).

The macula and ONH were evaluated, while the RNFL and GCC thicknesses were measured separately. The measurements were repeated three times for each eye to reduce measurement errors. The RNFL 3.40 protocol was used for peripapillary RNFL analysis, with the thickness measured at a diameter of 3.40 mm around the centre of the optic disc. The results were displayed on a colour map with customized software, with normative data adjusted for age and optic disc size. In the statistical analysis, RNFL thickness measurements were evaluated in four quadrants (superior, inferior, nasal, and temporal) (Fig. 1).

The macular thickness was measured using the retinal map protocol with a 5 × 5-mm area. Foveal (F) measurements were also taken (Fig. 2). GCC measurements consisted of one horizontal line scan 7 mm in length and 15 vertical line scans 7 mm in length taken at 0.5-mm intervals in a 6 × 6-mm area. The GCC thickness was defined as the distance between the inner limiting membrane and the outer border of the inner plexiform layer (Fig. 3). ONH measure-

ments were performed with 13 concentric circle ring scans and 12 radial line scans.

An LP was performed at least 24 h after OCT and the patients were not given medication before. The patients were placed in the left lateral decubitus position with their legs fully extended for CSF collection. All LPs were performed by the same physician (B. Ö.). Opening ICP over 25 cm H_2O was considered elevated. The CSF samples were evaluated microscopically and biochemically. In all patients, the CSF composition was normal, including cell count and CSF/serum albumin ratio.

Statistical analysis

Statistical analysis was carried out using NCSS 11 (NCSS Statistical Software, Kaysville, UT, USA). Mean, standard deviation, median, minimum and maximum values were given for continuous variables. The Kolmogorov-Smirnov test was performed to test for normal distribution of continuous variables. An independent sample t-test was used

for comparisons of continuous independent variables between the two groups. The Mann–Whitney U test was used to compare two independent groups for variables that did not conform to the normal distribution assumption. Correlations between OCT measurements and other variables were evaluated by nonparametric Spearman's correlation analysis. Regression analysis was done to assess the effect of body mass index (BMI) and CSF opening pressure on F and RNFL thickness. The linearity test was used to detect linear relationships between dependent and independent variables. The level of significance was accepted as $P < 0.05$.

Results

Nineteen newly diagnosed IIH patients were enrolled in the study. All the patients were obese (BMI > 25 kg/m²) women with a mean age of 34.79 ± 7 (20–44) years. Twenty-two age-matched women who had no significant medical or ocular conditions (mean age 33.14 ± 7.05 [20–45]) comprised the control

group. The demographic characteristics of the patients are shown in Tab. 1. The anterior segment findings and intraocular pressures were within normal limits in both the cases and the controls. Colour vision was within normal limits in all participants.

The mean RNFL and F thicknesses were significantly higher in the patient group compared to the control group (P < 0.01). There was no statistical difference in mean GCC thickness between the patient and control groups. In the comparison of the RNFL values of the patient and control groups by quadrants, the patient group had higher values in all quadrants. In addition, there was no significant difference in disc area in the patient group compared to the control group, but there was a statistically significant difference in rim area. The median cup/disc ratio and cup volume values were higher in the control group than in the patient group (Tab. 2).

There was a strong positive correlation between CSF opening pressure and Frisen score (rho = 0.869, P < 0.001). There were also moderately positive correlations between CSF opening pressure and BMI (rho = 0.653, P = 0.002) and duration of symptoms (rho = 0.458, P = 0.049). There was a moderately negative relationship between CSF opening pressure and visual field mean deviation (MD) levels (rho = −0.685, P = 0.001).

Multiple linear regression analysis was performed to determine which parameters were associated with RNFL and F thickness and to what degree. CSF opening pressure and BMI showed positive but non-significant associations with OCT parameters. The independent variables of CSF opening pressure (β = 0.205 t = 0.804) and BMI (β = 0.341 t = 1.335) were found to have positive effects on the dependent variable F thickness, at the level of 0.205 and 0.341, resp. The CSF opening pressure (β = 0.478 t = 1.817) and BMI (β = 0.141 t = 0.537) also had a positive relationship with peripapillary RNFL thickness at the 0.478 and 0.141 levels, resp.

In receiver operating characteristic curve analysis, the RNFL and F thicknesses were significant parameters in the prediction of IIH (P < 0.001). Areas under the curve were 1.00 for RNLF and 0.852 for F thickness (Fig. 4).

Discussion

In our study, the mean of RNFL and F thickness were found to be high in newly diagnosed and untreated IHH patients. Increased

peripapillary retinal thickness measured by OCT is closely associated with increased ICP in newly diagnosed IIH patients. Therefore, OCT could be a valuable diagnostic test in the very subjective assessment of papilloedema in patients suspected of having IIH. On the other hand, in our study GCC thickness was not found to be statistically different from the control group as previously reported. Our findings are consistent with a previous study carried out on female series with IIH in which the authors reported increased average RNFL thickness in patients compared with the controls. Their mean average RNFL thickness (130.16 ± 46.40 μm) was lower than that in the present study (135.89 ± 16.18 μm), which may be due to papilloedema grade (median grade of 2.0 vs. 3.0 in the present study) [13]. The difference may also be related to the fact that they performed LP 3–4 days before OCT, unlike in our study.

Skau et al evaluated diagnostic OCT as a marker of CSF opening pressure in patients with IIH. The study comprised 20 newly diagnosed IIH patients, 21 long-term IIH patients and 20 healthy controls. Their results showed that increased peripapillary retinal thickness measured by OCT was associated with elevated ICP in newly diagnosed IIH patients. OCT may therefore serve as a valuable supplement for subjective papilloedema assessment in patients with IIH. These findings suggest that OCT may help to determine the severity of ICP in addition to facilitating the diagnosis of papilloedema in the acute phase. However, for long-term IIH patients who have previously been treated, OCT appears to be of limited value [14].

In some studies, including mixed groups of acute and chronic patients, RNFL thickness was reported to be similar to the control group [15]. In accordance with previous studies in literature, we found a correlation between CSF opening pressure and Friesen score, RNFL and F thickness at 1 mm [16–18]. We also found a negative correlation between visual field MD value and CSF opening pressure. We believe that these findings in OCT can help clinicians to predict CSF opening pressure before LP in early IIH. Discrepant results between studies may be related to the heterogeneity of patients and the timing of LP. In the study performed by Heckman et al [19], LP was performed before OCT. Anticipating that OCT findings may be altered due to the decrease in CSF pressure following LP; we also performed LP at least

24 h after OCT in our study. It is well known that there may be temporary improvement of IIH symptoms immediately after LP; a post-LP headache suggests that the puncture can transiently lower CSF pressure. Furthermore, there is evidence that RNFL thickness can decrease after LP [20].

Body mass index and weight gain as a function over the last year increase the risk of IIH development. BMI > 40 kg/m^2 has been shown to increase the risk of IIH-induced vision loss [21]. Berdahl et al demonstrated a linear relationship between BMI and CSF opening pressure [22]. They showed that a BMI of 18–39 resulted in a 37.7% increase in CSF opening pressure. Consistent with their results, we observed a moderately positive correlation between CSF opening pressure and BMI (r = 0.653, P = 0.02). Our regression analysis revealed that each 1 cm H$_2$O increment in CSF opening pressure increased mean RNFL and F thickness by 0.478 μm and 0.205 μm, resp.

Labib and Rebolleda reported that every 10 μm increase in mean RNFL thickness corresponded to declines in visual field MD of 0.56 and 0.60 dB, resp. [13,16]. Consistent with their results, in the present study we detected a moderate negative correlation (rho = –0.685, P = 0.001) between CSF opening pressure and visual field MD value.

One strength of our study was that all patients were enrolled when the clinical diagnosis was new, before any therapy was initiated. In order to prevent loss of vision it is essential to recognize the symptoms and identify these patients in the early stages. Furthermore, CSF pressure was measured during the same hospital stay as the OCT assessments. This allowed us to analyze the retinal sequelae of elevated CSF pressure and papilloedema early in the course of the disease. The limitations of the present study are the small population size and unknown interval from disease onset to study inclusion. As IIH is a relatively infrequent clinical entity, large numbers of qualified patients are difficult to recruit at one centre.

The main limitation of OCT is that it analyzes structure rather than function and therefore, there is approximately a 2-week lag between optic nerve damage and visible thinning of the GCC, which can potentially limit its utility at a patient's initial presentation [23,24]. The current study showed that the papilloedema grade correlated significantly with the average initial RNFL thickness but not with the average GCC thickness. We

attributed the lack of a difference in GCC thickness between newly diagnosed IIH patients and controls to the fact that none of our patients exhibited macular oedema or optic atrophy. We believe that this may be related to the disease stage.

In conclusion, our study confirms that OCT is a non-invasive, quantitative method for detecting papilloedema in IIH patients. Increased peripapillary retinal thickness measured by OCT is closely associated with increased ICP in newly diagnosed IIH patients. Therefore, OCT could be a valuable diagnostic test in the very subjective assessment of papilloedema in patients suspected of having IIH.
